Galectin-1 (Gal-1)-binding to Gal-1 ligands on immune and endothelial cells can influence melanoma development through dampening antitumor immune responses and promoting angiogenesis. However, whether Gal-1 ligands are functionally expressed on melanoma cells to help control intrinsic malignant features remains poorly understood. Here, we analyzed expression, identity, and function of Gal-1 ligands in melanoma progression. Immunofluorescent analysis of benign and malignant human melanocytic neoplasms revealed that Gal-1 ligands were abundant in severely dysplastic nevi, as well as in primary and metastatic melanomas. Biochemical assessments indicated that melanoma cell adhesion molecule (MCAM) was a major Gal-1 ligand on melanoma cells that was largely dependent on its N-glycans. Other melanoma cell Gal-1 ligand activity conferred by O-glycans was negatively regulated by α 2,6 sialyltransferase ST6GalNAc2. In Gal-1-deficient mice, MCAM-silenced (MCAM^{KD}) or ST6GalNAc2-overexpressing (ST6^{O/E}) melanoma cells exhibited slower growth rates, underscoring a key role for melanoma cell Gal-1 ligands and host Gal-1 in melanoma growth. Further analysis of MCAM^{KD} or ST6^{O/E} melanoma cells in cell migration assays indicated that Gal-1 ligand-dependent melanoma cell migration was severely inhibited. These findings provide a refined perspective on Gal-1/melanoma cell Gal-1 ligand interactions as contributors to melanoma malignancy.

INTRODUCTION

Galectin-1 (Gal-1) is one of the 15 evolutionarily conserved S-type lectins that bind lactosamine sugars on discrete cell membrane proteins and extracellular matrix (ECM) components (Cho and Cummings, 1995; Camby *et al.*, 2006). Gal-1 is expressed by effector T and B cells, inflammatory macrophages, decidual natural killer cells, FoxP3⁺ regulatory T cells, and endothelial cells (ECs), where it has a key role in suppressing innate and adaptive immune responses (Baum *et al.*, 1995; Rabinovich *et al.*, 1998; Zuniga *et al.*, 2001; Koopman *et al.*, 2003; Blois *et al.*, 2007; Garin *et al.*, 2007;

Kopcow *et al.*, 2008; Thijssen *et al.*, 2008; Ouyang *et al.*, 2011). Gal-1 is also elevated in certain tumor cells, where it promotes tumor growth and cancer progression by immune tolerizing effects on dendritic cells and effector T cells and by angiogenesis via direct interactions with ECs (Rubinstein *et al.*, 2004; Thijssen *et al.*, 2006, 2010; Demydenko and Berest, 2009; Ilarregui *et al.*, 2009; Lefranc *et al.*, 2011; Mathieu *et al.*, 2012; Cedeno-Laurent *et al.*, 2012b,c; Laderach *et al.*, 2013). One recent report identified Gal-1 on mesenchymal stem cells as a positive regulator of tumor growth (Szebeni *et al.*, 2012). Gal-1 elicits its effects via binding to glycoprotein (or glycolipid) counter-receptor ligands that confer a Gal-1 ligand activity and subsequent initiation of functional activities, including adhesion/migration, immune suppression, and angiogenesis. Our descriptions herein define a Gal-1 ligand as a preferred membrane protein bearing poly-N-acetyllactosamine(s) on asparagine (N)- and/or serine/threonine (O)-glycans in an optimal orientation for Gal-1-binding. Understanding how Gal-1 ligands regulate tumor growth could provide important insights into the development of anticancer therapeutics and lay the foundation for generation of reliable diagnostic markers for tumor growth and metastasis.

Malignant melanoma is a well-documented tumor model leveraging Gal-1/Gal-1 ligand interactions. Complete ablation of melanoma- and host-derived Gal-1 expression severely

limits melanoma growth (Rubinstein *et al.*, 2004; Thijssen *et al.*, 2006; Toscano *et al.*, 2007; Thijssen *et al.*, 2010; Banh *et al.*, 2011; Cedeno-Laurent *et al.*, 2012b). Gal-1 facilitates melanoma immune evasion by reducing the number of IFN- γ -producing T helper cells and cytolytic T cells, including melanoma-specific cytolytic T cells (Rubinstein *et al.*, 2004; Toscano *et al.*, 2007; Ilarregui *et al.*, 2009; Cedeno-Laurent *et al.*, 2012b). Depending on local concentrations, Gal-1 can engage dendritic cell/T-cell Gal-1 ligands CD7, CD43, and/or CD45 and either initiate a proapoptotic activity or a regulatory signaling circuit (Perillo *et al.*, 1995; Pace *et al.*, 2000; Nguyen *et al.*, 2001; Suzuki *et al.*, 2005a; Hernandez *et al.*, 2006; Fulcher *et al.*, 2009; Cedeno-Laurent *et al.*, 2010, 2012a,b). Alternatively, melanoma- and host-derived Gal-1 bind ECs and support a number of proangiogenic activities, including EC survival, migration, and capillary formation *in vitro* and *in vivo* (Thijssen *et al.*, 2006, 2008, 2010; Mathieu *et al.*, 2012; Szebeni *et al.*, 2012; Laderach *et al.*, 2013; Croci *et al.*, 2014). Gal-1-binding to CD146, otherwise known as melanoma cell adhesion molecule (MCAM), on ECs, in fact, can encourage survival (Jouve *et al.*, 2013). Although Gal-1/Gal-1 ligand interactions clearly promote melanoma growth through immunosuppressive and proangiogenic mechanisms, the direct impact of Gal-1 on melanoma cells is not fully understood. One study shows that Gal-1 on melanoma cells can mediate homotypic cell–cell interactions, in part, via binding to Gal-1 ligand, 90K/MAC-2BP (Tinari *et al.*, 2001).

Here, we performed a comprehensive assessment into expression, identity, and regulation of Gal-1 ligands on melanoma cells and related malignant behavior. Dual immunofluorescence (IF) analysis of Gal-1 ligand expression using an innovative Gal-1 probe showed that malignant melanomas, including melanoma *in situ*, radial and vertical growth phase melanomas, and melanoma metastases, contained an abundance of Gal-1 ligand that was largely absent on epidermal melanocytes in normal human skin, in benign nevi, and in uninvolved skin adjacent to the malignant lesion. Of note, dermal melanocytic nests in an atypical nevus with spindle cell proliferation, inflammation, and features of regression were also positive for Gal-1 ligands. Biochemical analysis showed that MCAM, which, itself, has been implicated in melanomagenesis (Xie *et al.*, 1997; Jean *et al.*, 1998; Mills *et al.*, 2002), was one of the major melanoma cell Gal-1 ligands and was largely dependent on its N-glycans for Gal-1-binding. We found that O-glycans, to a lesser extent, also contributed to total melanoma cell Gal-1 ligand activity. Gene expression analysis revealed that α 2,6 sialyltransferase ST6GalNAc2, whose α 2,6 sialylation activity on a Core 1 O-glycan prevents synthesis of extended Core 2 O-glycans that bind Gal-1 (Nguyen *et al.*, 2001; Earl *et al.*, 2010), was significantly downregulated in malignant melanoma cells compared with human epidermal melanocytes (HEMs). When MCAM-silenced (MCAM^{KD}) or ST6GalNAc2-overexpressing (ST6^{O/E}) melanoma cells were grown in mice deficient in Gal-1, tumor growth was significantly reduced. Similarly, Gal-1 ligand-dependent migration of MCAM^{KD} or ST6^{O/E} melanoma cells on ECM was inhibited, suggesting that Gal-1

ligand activity may be promoted by high MCAM and low ST6GalNAc expression. Together, these data demonstrate a key role for melanoma cell Gal-1 ligands, including MCAM, and of Gal-1 ligand regulator, ST6GalNAc2, as functional correlates with malignant behavior.

RESULTS

Expression of Gal-1 ligands is elevated in malignant melanomas

To investigate the relationship between Gal-1 ligand expression and malignant melanoma, we used dual IF to determine Gal-1 ligand expression on benign and malignant melanocytes in human biological specimens. We stained for S100 (in red), a marker of melanocyte-lineage cells, and Gal-1 ligands with mouse Gal-1–human immunoglobulin chimera (Gal-1hFc) (in green) or dmGal-1hFc (a nonbinding double mutant control) as previously described (Cedeno-Laurent *et al.*, 2012b). Because S100 is also found in Langerhans cells, this staining strategy was intentionally implemented to encompass a predominant epidermal immune cell subset that could potentially bear Gal-1 ligand.

We found that S100⁺ cells encompassing both Langerhans cells and melanocytes in the epidermis of normal skin and a benign nevus were negative for Gal-1 ligand expression (Figure 1a and b). However, melanocyte-lineage cells in a melanoma *in situ* were positive for both S100 and Gal-1 ligand (merged in yellow) (Figure 1c). Western blotting lysates from normal HEMs and human melanoma G361 cells (Figure 1d) and FACS staining of primary human metastatic melanoma cells and human G361 melanoma cells (Figure 1e) with Gal-1hFc revealed conspicuous elevation in Gal-1 ligand(s) on melanomas. Of note, detection of surface Gal-1 ligands was not significantly masked by well-described melanoma cell galectins, Gal-1, -3, and -9 (Braeuer *et al.*, 2012), as we did not stain appreciable levels of Gal-1, -3, and -9 on the melanoma cell surface (Supplementary Figure S1 online). To verify Gal-1 ligand staining with statistical significance, IF analysis was performed on tissue microarrays (containing 56 primary and 20 metastatic melanomas and 24 benign pigmented nevi) using Gal-1hFc (in green). In this case, dual IF staining was not employed because of the potential variations in S100 expression by metastatic melanoma cells (Aisner *et al.*, 2005). Data demonstrated significantly higher mean intensities of Gal-1 ligand staining on primary and metastatic melanomas compared with the levels on benign nevi ($P < 0.001$) (Figure 1f).

Additional dual IF staining of a premalignant nevus with atypia and inflammation showed that dermal S100⁺ melanocytic nests were strongly positive for Gal-1 ligand, suggesting that melanocyte localization to dermis may correspond with Gal-1 ligand upregulation. Yet, dual IF staining of malignant melanomas, including radial and vertical growth phase subsets, showed that malignant melanocytic nests located in the epidermis and dermis were strongly positive for Gal-1 ligand(s) (Figure 2b–d). Of note, epidermal melanocytes outside of the tumor margin did not stain for Gal-1 ligand (Figure 2b and c), highlighting the capacity of this method to distinguish Gal-1 ligand⁺ malignant melanocytes from benign epidermal counterparts.

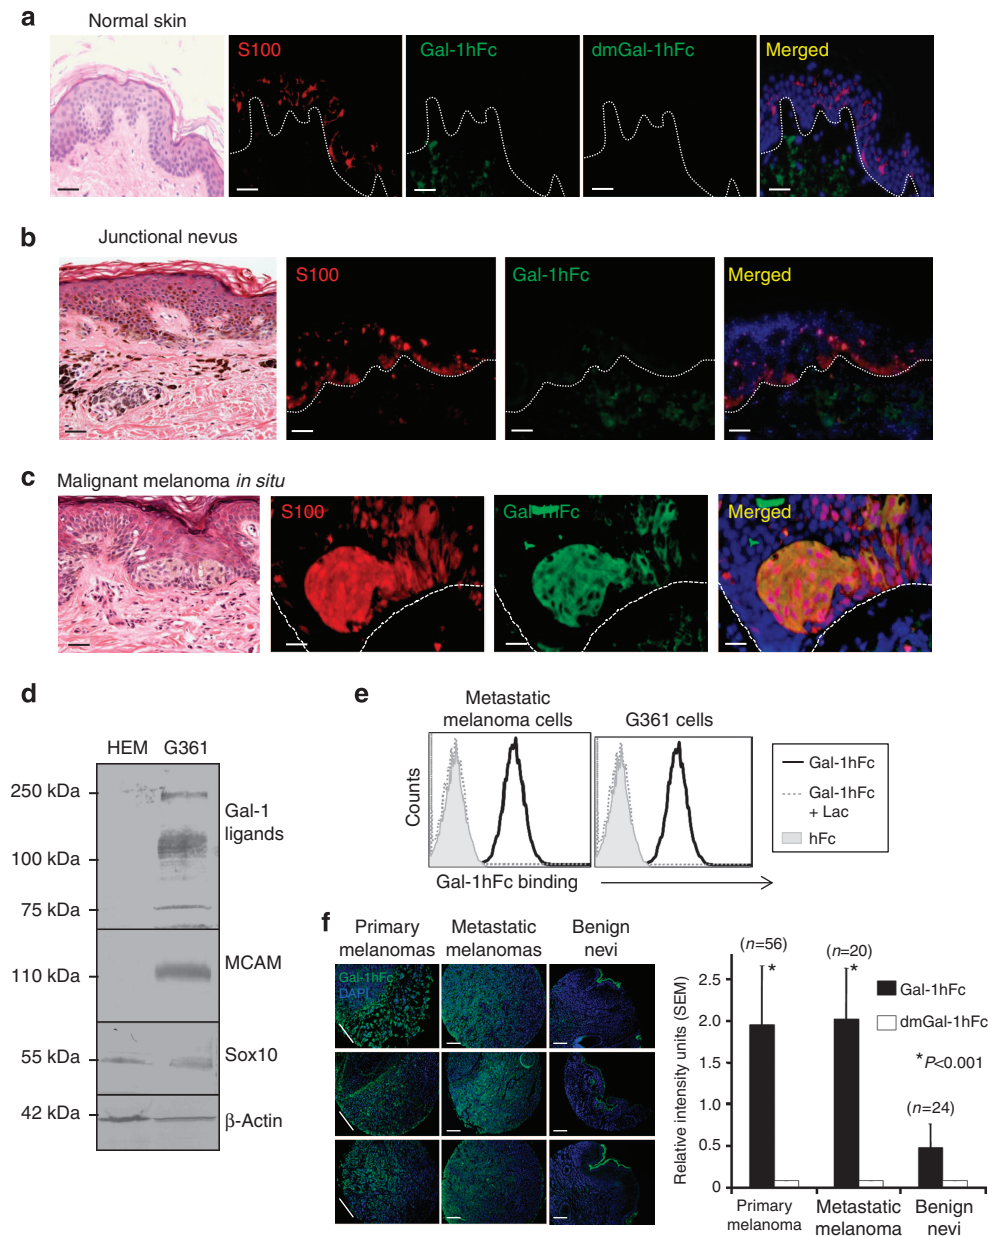

Figure 1. Galectin-1 (Gal-1) ligands are differentially expressed on normal human melanocytes and human melanoma cells. Dual immunofluorescence (IF) analysis of Gal-1 ligands with Gal-1hFc (in green) or dmGal-1hFc control and S100 with anti-S100A-B (in red) was performed on (a) formalin-fixed, paraffin-embedded (FFPE) sections of normal human skin (b), a benign junctional nevus, and (c) melanoma *in situ*. (d) Western blot analysis of Gal-1 ligands (with Gal-1hFc), melanoma cell adhesion molecule (MCAM) polypeptide, SOX10, and β -actin in human epidermal melanocytes (HEMs) and G361 melanoma cell lysates was performed. (e) Primary melanoma cells and G361 melanoma cells were FACS analyzed with Gal-1hFc or controls. (f) IF analysis of Gal-1 ligands was performed on tissue microarrays (TMAs) containing primary ($n = 56$) and metastatic melanomas ($n = 20$) and benign nevi ($n = 24$). * $P < 0.001$, statistical significance compared with benign nevi. Scale bars = 100 μ m.

MCAM is a Gal-1 ligand on human melanoma cells

To identify potential Gal-1 ligands on melanoma cells, we used protein G-affinity chromatography and western blotting to interrogate Gal-1-binding proteins in human melanoma cells using Gal-1hFc as a probe (Cedeno-Laurent *et al.*, 2010, 2012a). We detected major Gal-1-stained bands in the range of 110–150 kDa as well as at 250 kDa in melanoma short-term cultures and SK-MEL, SK-MEL2, and G361 melanoma

cell lines (Figures 1d and 3a). MCAM blotting was performed in parallel to control for detection of a common melanoma-specific marker (Figure 3a). Negative control blots probed with secondary antibody alone, with Gal-1hFc and 50 mM lactose, or with dmGal-1hFc showed no staining, confirming carbohydrate dependence and Gal-1 ligand authenticity.

Protein G-affinity chromatography of G361 melanoma cell lysate with Gal-1hFc or dmGal-1hFc control and tandem mass

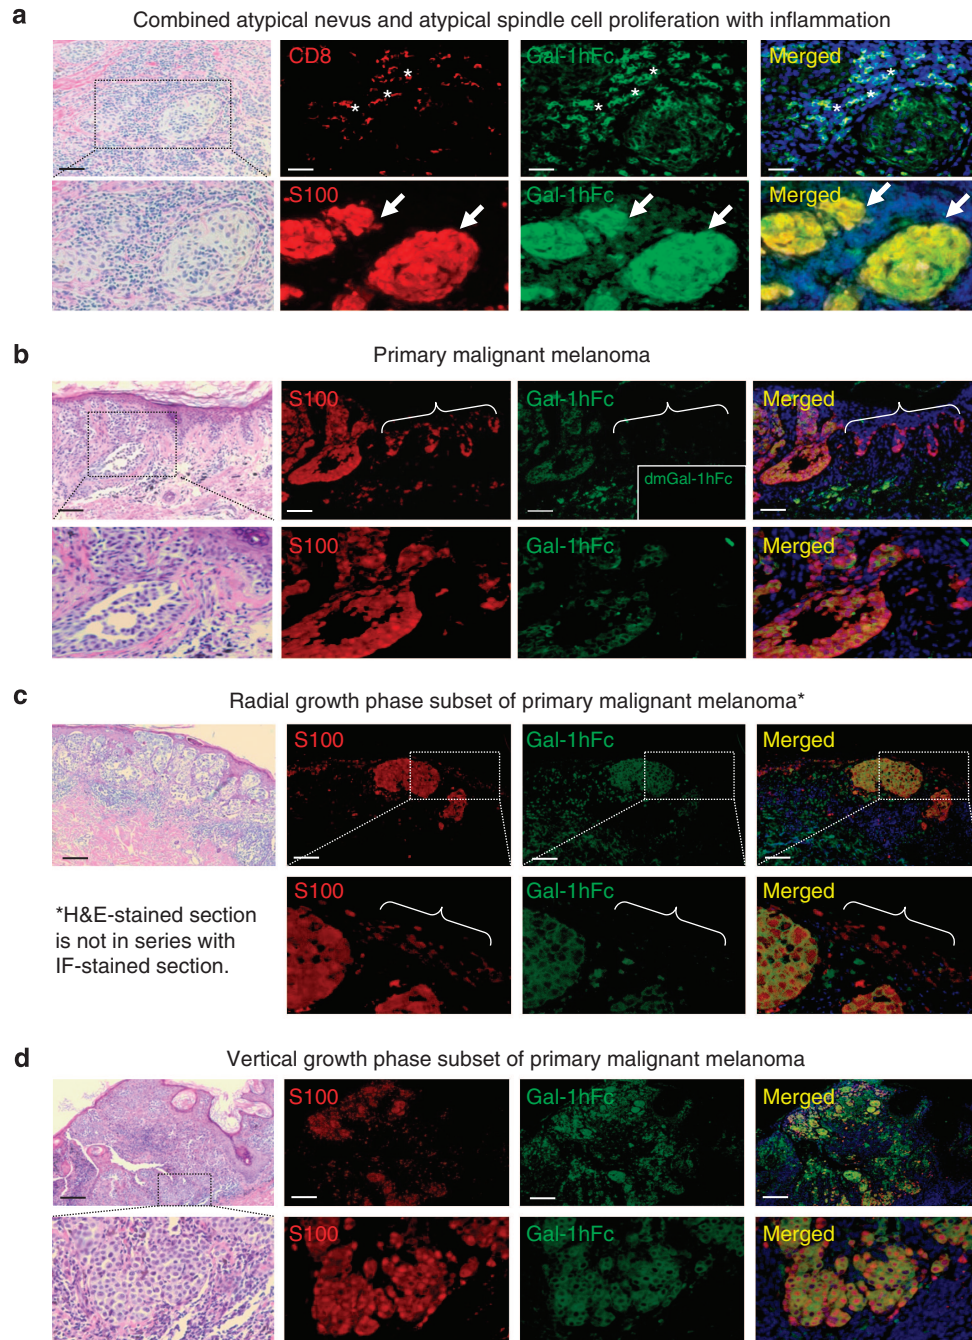

Figure 2. A premalignant melanocytic tumor and malignant melanomas are strongly positive for galectin-1 (Gal-1) ligands. Dual immunofluorescence (IF) analysis of Gal-1 ligands (in green) and CD8 or S100 (in red) was performed on formalin-fixed, paraffin-embedded (FFPE) sections of (a) a combined atypical nevus and an atypical spindle cell proliferation with inflammation (asterisks indicate Gal-1 ligand⁺ CD8⁺ cells and arrows indicate Gal-1 ligand⁺ S100⁺ dermal nests). Dual IF staining of (b) primary cutaneous melanomas, including (c) radial and (d) vertical growth phase subsets, was also performed. Brackets in b (upper panel) and c (lower panel) indicate margin tissue where nonmalignant epidermal S100⁺ cells were Gal-1 ligand⁻. H&E, hematoxylin and eosin. Scale bars = 100 μm and photomicrographs enlarged in the lower panels as indicated.

spectrometry analysis of corresponding eluates revealed several potential Gal-1 ligand candidates. The candidate with the highest number of peptide matches corresponding to a membrane protein was MCAM (Figure 3b). Examination of the entire list of protein matches indicated the presence of other known human Gal-1 ligand(s), including, in descending order,

galectin-3-binding protein (90K/MAC-2BP), lysosomal-associated membrane protein-1 and -2 (LAMP-1/2), and carcinoembryonic antigen (Wojnarowska *et al.*, 1996; Tinari *et al.*, 2001) (Supplementary Figure S2 online). Validation of MCAM as a Gal-1 ligand was ascertained by blotting Gal-1hFc eluate from G361 cell lysates with anti-MCAM antibody.

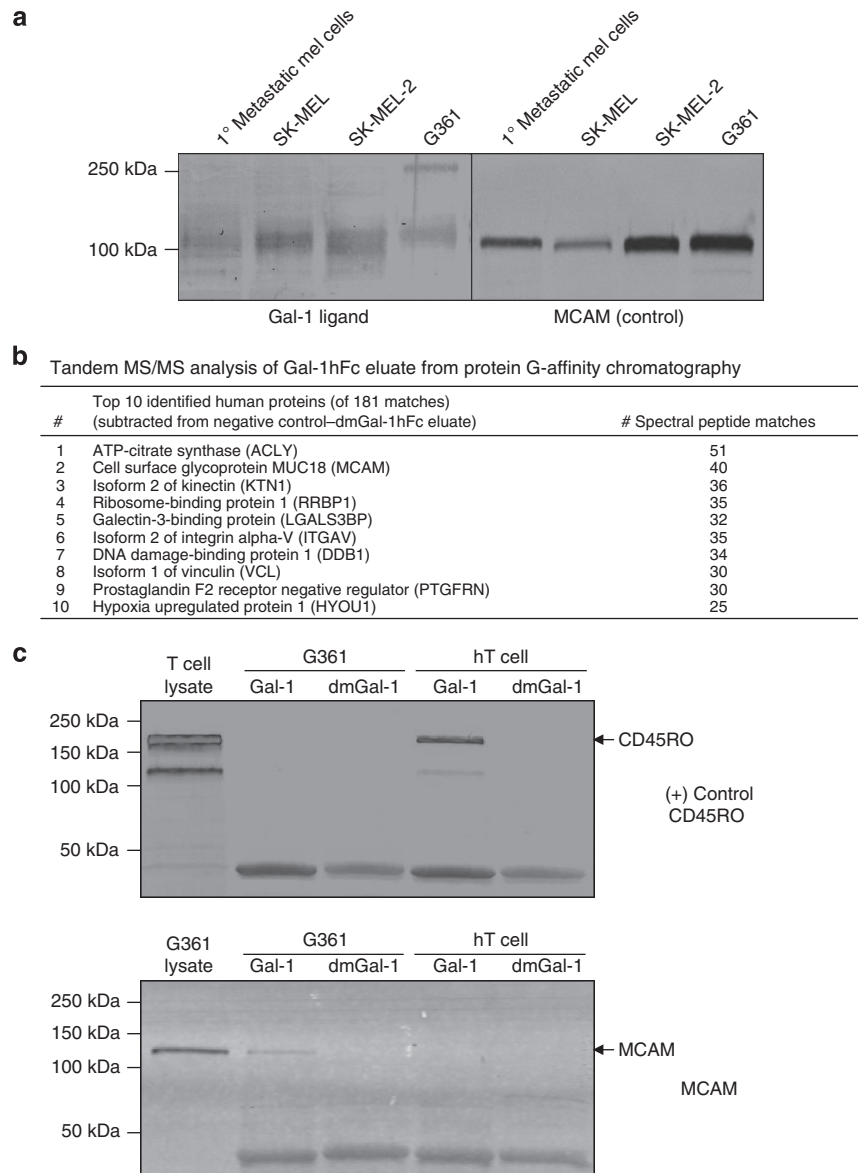

Figure 3. Affinity purification of candidate galectin-1 (Gal-1) ligands from human melanoma cells implicates melanoma cell adhesion molecule (MCAM) as a major Gal-1 ligand. (a) Primary metastatic melanoma (mel) cells or melanoma cell line lysates were blotted with Gal-1hFc or control anti-MCAM. As shown in (b), the top 10 proteins and corresponding number of peptide matches identified by tandem mass spectrometry (MS/MS) of elutes from protein G affinity chromatography with Gal-1hFc or negative control dmGal-1hFc and G361 cell lysate are listed. (c) Control activated human T-cell or melanoma G361 cell lysate and eluates from protein G affinity chromatography with Gal-1hFc or negative control dmGal-1hFc were blotted with anti-CD45RO or anti-MCAM. Arrows indicate the presence of T-cell CD45RO at 190 kDa and melanoma cell MCAM at 120 kDa.

Eluates from nonbinding dmGal-1hFc control and from Gal-1hFc-affinity chromatography of Gal-1 ligand⁺ human activated T-cell lysate were examined in parallel to control for Gal-1 specificity. In Figure 3c, a known human T-cell Gal-1 ligand, CD45RO, was purified in Gal-1hFc-eluate, whereas MCAM was isolated from G361 cell lysate. On the other hand, dmGal-1hFc did not purify CD45RO or MCAM, showing dependence on functional Gal-1 (Figure 3c). We additionally immunoprecipitated 90K/MAC-2BP from human A375 melanoma cells and blotted with Gal-1hFc to demonstrate that Gal-1hFc could recognize a human Gal-1 ligand previously

identified on A375 cells using human Gal-1 (Supplementary Figure S3 online) (Iacobelli *et al.*, 1986; Tinari *et al.*, 2001).

To solidify MCAM as a Gal-1 ligand, western blotting anti-MCAM immunoprecipitates of G361 (Figure 4a) or primary melanoma (Figure 4b) cell lysates with Gal-1hFc was also performed and demonstrated that MCAM indeed binds Gal-1. Anti-MCAM immunoprecipitates from A375 cells were blotted with Gal-1hFc, demonstrating that Gal-1-binding glycans were similarly displayed on MCAM (Figure 4c). Anti-MCAM immunoprecipitates blotted with anti-MCAM confirmed the presence of MCAM protein at 120 kDa

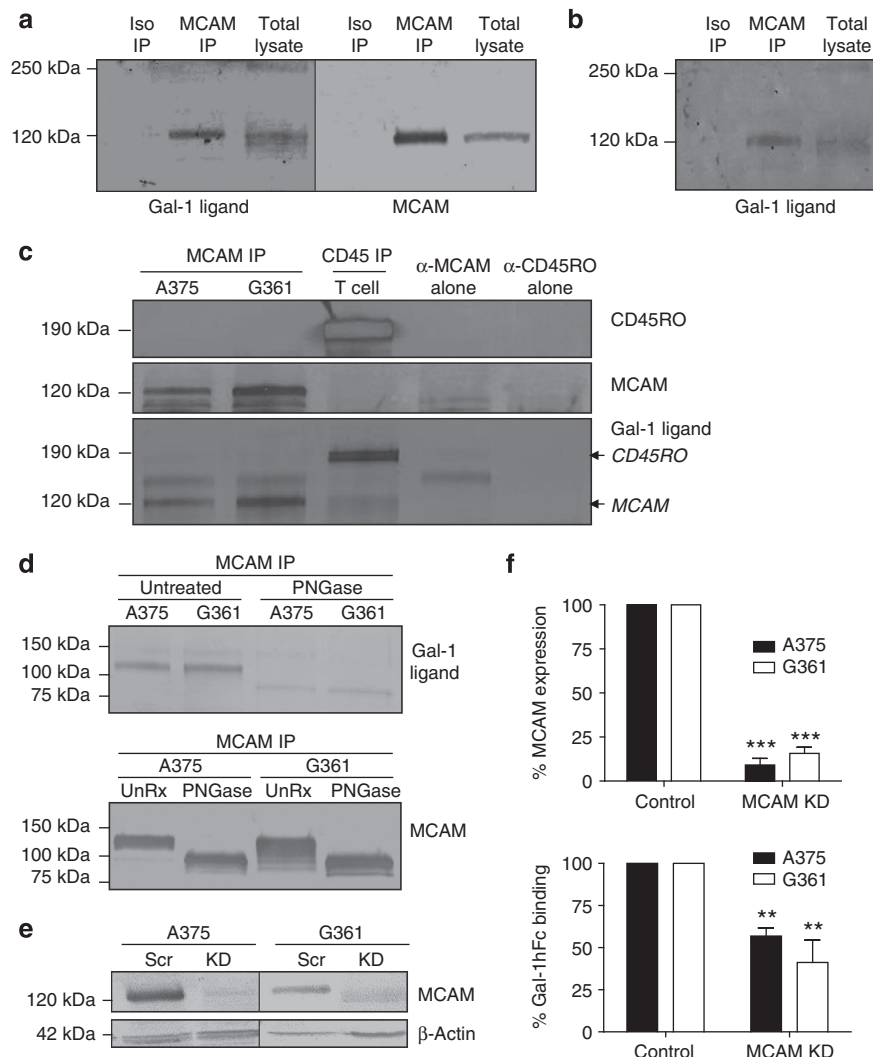

Figure 4. N-glycosylated melanoma cell adhesion molecule (MCAM) binds galectin-1 (Gal-1) and is a major contributor of total melanoma cell ligand activity.

(a) Anti-MCAM immunoprecipitates from G361 or (b) primary melanoma cell lysates were blotted with Gal-1hFc or anti-MCAM. IP, immunoprecipitation. (c) Anti-CD45RO immunoprecipitates from activated T-cell lysate or anti-MCAM immunoprecipitates from A375 and G361 cell lysates were blotted with anti-CD45RO, anti-MCAM, or Gal-1hFc. (d) Anti-MCAM immunoprecipitates from A375 and G361 cell lysates were treated with PNGase and blotted with Gal-1hFc or anti-MCAM. (e) Scr or MCAM^{KD} A375 and G361 cell lysates were blotted with anti-MCAM or anti-β-actin. (f) Scr or MCAM^{KD} A375 and G361 cells were analyzed for MCAM and Gal-1 ligand by flow cytometry. ** $P < 0.01$ and *** $P < 0.001$, statistical significance compared with Scr control. All experiments were performed three times.

(Figure 4a and c). Control immunoprecipitates with either anti-MCAM or anti-CD45RO in the absence of lysate revealed nonspecific stained Ig bands at 100 and 150 kDa (Figure 4c). As expected, anti-CD45RO immunoprecipitate from human T cells was blotted with Gal-1hFc, confirming capacity of Gal-1hFc to authenticate a hallmark human Gal-1 ligand (Figure 4c) (Cedeno-Laurent et al., 2012a). In all, affinity chromatography, western blotting, and immunoprecipitation approaches helped identify MCAM as a putative Gal-1 ligand.

As MCAM has eight potential N-glycosylation sites (Lehmann et al., 1989), we examined whether MCAM Gal-1-binding determinants resided on N-linked glycans. We treated anti-MCAM immunoprecipitates with PNGase, separated products by SDS-PAGE, and blotted with Gal-1hFc or controls to detect Gal-1-binding MCAM. PNGase-treated anti-

MCAM immunoprecipitates were also blotted with anti-MCAM to control for MCAM detection. PNGase treatment lowered MCAM size to ~85 kDa, indicative of de-N-glycosylation, and eliminated its Gal-1-binding activity (Figure 4d). To determine the relative contribution of MCAM Gal-1 ligand activity, we analyzed Gal-1 ligand expression in A375 and G361 melanoma cells knocked down (^{KD}) for MCAM expression. Using western blot and FACS analysis, we showed a significant reduction in MCAM expression by 90% ($P < 0.001$; Figure 4e) and, compared with Scr controls, MCAM^{KD} cell variants exhibited a 40% reduction in Gal-1 ligand activity (Figure 4f). Furthermore, dependency of MCAM for binding human Gal-1 was validated by FACS analysis and confirmed the capacity of our Gal-1hFc formulation to similarly detect human Gal-1 ligands

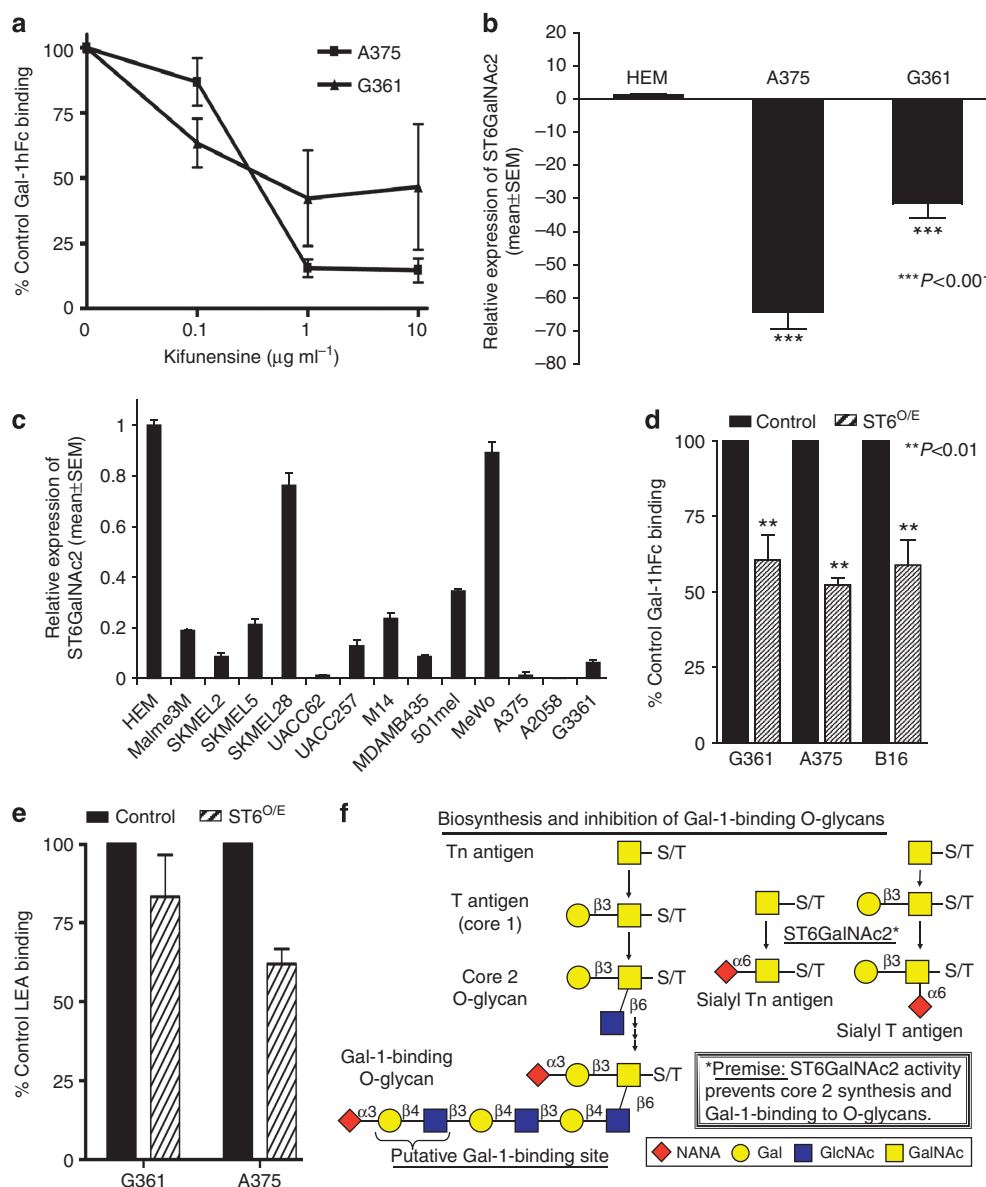

Figure 5. ST6GalNAc2 is downregulated in melanoma cells and is a putative regulator of O-glycan-dependent galectin-1 (Gal-1) ligand activity.

(a) Kifunensine-treated A375 and G361 cells were assayed for Gal-1 ligand activity by flow cytometry with Gal-1hFc or controls. Real-time quantitative reverse-transcriptase-PCR (RT-qPCR) analysis was performed on (b) human epidermal melanocytes (HEMs), G361, and A375 cells and (c) 11 other melanoma cell lines. Relative ST6GalNAc2 expression level was normalized to expression in HEMs over three experiments and expressed as mean ± SEM. (d) Gal-1hFc and (e) *Lycopersicon esculentum* lectin (LEA) binding of control or ST6^{O/E} melanoma cells was analyzed by flow cytometry. (f) An illustration of ST6GalNAc2 role on the biosynthesis and putative inhibition of Gal-1-binding to O-glycans. ** $P < 0.01$ and *** $P < 0.001$, statistical significance compared with untreated controls or HEMs.

(Supplementary Figure S4 online) (Tsai *et al.*, 2008). Control treatments containing 50 mM lactose or probing with dmGal-1hFc did not detect any measurable Gal-1 ligand. These data suggested that MCAM through its N-glycosylations was a major Gal-1 ligand on melanoma cells.

α2,6 sialyltransferase ST6GalNAc2 is a negative regulator of Gal-1 ligand activity in melanoma cells

As MCAM silencing on melanoma cells did not completely lower Gal-1 ligand activity, we subsequently ascertained whether other glycoconjugates could contribute to total

cellular ligand activity. Bromelain protease treatment before assaying for Gal-1 ligand activity on A375 and G361 melanoma cells indicated that nearly all of the cellular activity was contributed by glycoproteins with a negligible contribution by glycolipids (Supplementary Figure S5a online). Hence, we then treated melanoma cells with an effective complex N-glycan inhibitor, kifunensine, and found that Gal-1 ligand activity was significantly reduced by 80 and 50% in A375 and G361 cells, respectively ($P < 0.001$; Figure 5a). This suggested that any residual activity above the protease treatment level was likely due to O-glycans. In a

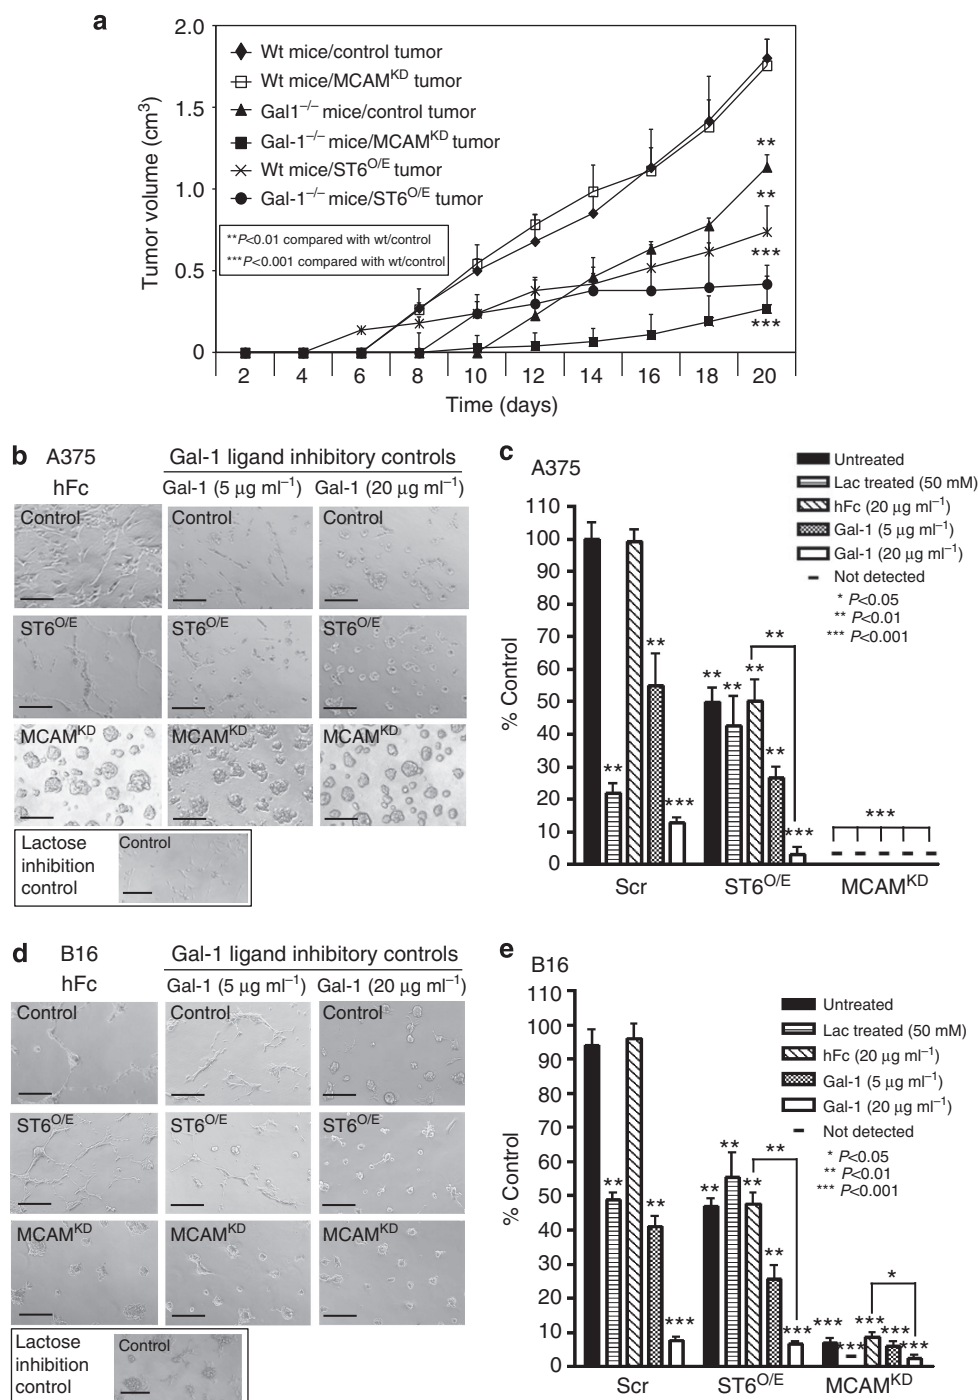

Figure 6. *In vivo* growth of melanoma cells and migration of melanoma cells on Matrigel are regulated, in part, by host galectin-1 (Gal-1) and on melanoma cell Gal-1 ligands. (a) Wild-type (WT) or Gal-1^{-/-} mice were inoculated subcutaneously (s.c.) with control, ST6^{O/E}, or MCAM^{KD} B16 cells and monitored for tumor growth. Mean tumor volumes (SEM) ($n=8$ /group) were calculated and plotted against time. (b–e) Control, ST6^{O/E}, or MCAM^{KD} A375 and B16 melanoma cells preblocked with Gal-1hFc, hFc, or lactose were assayed for formation of tube-like structures on Matrigel. Tube-like structures were illustrated in representative phase photomicrographs (scale bars = 100 μm). The number of tube-like structures was expressed as % Control hFc-treated cells. * $P<0.05$, ** $P<0.01$, and *** $P<0.001$, statistical significance compared with hFc-control cells. Data were collected from at least three experiments.

control experiment, binding of phytohemagglutinin, which binds tetra-antennae of complex N-glycans, was completely eliminated, validating N-glycan removal (Supplementary Figure S5b online). We next examined whether the membrane protein LAMP-1 identified by Gal-1 affinity

chromatography and bearer of putative O-glycan sites could also serve as a Gal-1 ligand. We observed that LAMP-1 immunoprecipitates from melanoma cell avidly bound Gal-1 (Supplementary Figure S6 online). These data suggested that LAMP-1, which has been shown to display O-glycans and

bind Gal-1 (Skrincosky et al., 1993; Ohannesian et al., 1994), could contribute to melanoma cell Gal-1 ligand activity.

Recent data suggest that high expression of α 2,6 sialyltransferase ST6GalNAc2, which transfers sialic acid in a α 2,6 linkage to *N*-acetylgalactosamine on Core 1 O-glycans (Marcos et al., 2004), prevents Gal-3-binding to unmodified Core 1 O-glycan (Murugaesu et al., 2014). As Gal-1 binds extended Core 2 O-glycans, we investigated whether ST6GalNAc2 could neutralize O-glycan-dependent Gal-1 ligand activity. We hypothesized that ST6GalNAc2 was differentially expressed between Gal-1 ligand⁻ HEM cells and Gal-1 ligand⁺ melanoma cells. Real-time quantitative reverse-transcriptase-qPCR analysis revealed that, compared with expression in HEMs, ST6GalNAc2 was downregulated in A375 and G361 cells by 65- and 30-fold, respectively (Figure 5b). In fact, ST6GalNAc2 was uniformly downregulated in 13 melanoma cell lines (Figure 5c). To examine the negative role of ST6GalNAc2 in Gal-1 ligand activity, we generated G361 and A375 cells, along with B16 melanoma cells stably overexpressing ST6GalNAc2 and assayed for Gal-1 ligand activity. ST6GalNAc2-overexpressing (ST6^{O/E}) cell variants exhibited ~30% lower Gal-1 ligand activity compared with vector control cells ($P < 0.01$; Figure 5d). Assaying for binding of *Lycopersicon esculentum* lectin, which binds poly-*N*-acetyllactosamines known for binding Gal-1 (Skrincosky et al., 1993; Ohannesian et al., 1994; Nguyen et al., 2001; Earl et al., 2010), further showed that ST6^{O/E} cell variants expressed reduced levels of poly-*N*-acetyllactosamines (Figure 5e). These data suggested that ST6GalNAc2 could potentially serve as a negative regulator of Gal-1-binding to O-glycans (Figure 5f).

Melanoma cell Gal-1 ligands contribute to tumor formation in mice

To investigate whether Gal-1 collaborates with MCAM or other Gal-1 ligands regulated by ST6GalNAc2 to trigger melanoma growth, we assayed the growth of MCAM-silenced (MCAM^{KD}) (Supplementary Figure S7 online) or ST6^{O/E} B16 melanoma cells in mice deficient in Gal-1. To rule out intrinsic alterations in proliferation due to silencing/overexpression methods, we compared MCAM^{KD} or ST6^{O/E} B16 cell proliferation with vector controls in a carboxyfluorescein succinimidyl ester dilution assay and found no differences in proliferation rates (Supplementary Figure S8 online). Assessments on longitudinal growth of control, MCAM^{KD}, and ST6^{O/E} B16 cells in wild-type mice showed that MCAM^{KD} tumors grew at similar rates as control cells, whereas ST6^{O/E} tumors exhibited slower growth ($P < 0.01$; Figure 6a). Prior data, in fact, show that melanoma cells expressing variable levels of MCAM grow at similar rates in mice (Wu et al., 2008), and this may be associated with the pleiotropic role of MCAM in cancer development (Wang and Yan, 2013). However, as expected, MCAM^{KD} or ST6^{O/E} tumors when inoculated in Gal-1^{-/-} mice grew at significantly slower velocities ($P < 0.001$; Figure 6a). These data suggested that collaboration of host-derived Gal-1 and melanoma cell Gal-1 ligands, governed by either MCAM or ST6GalNAc2 expression, was necessary for optimal melanoma growth.

To further investigate MCAM and ST6GalNAc2 in malignant potential of melanoma cells, we examined the ability of MCAM^{KD} and ST6^{O/E} melanoma cells to migrate in a well-described Matrigel assay (Frank et al., 2011). As the ECM used is rich in Gal-1 (Crocì et al., 2012) (Supplementary Figure S9 online), we were able to assay MCAM^{KD} or ST6^{O/E} melanoma cell migration in a Gal-1 ligand-dependent manner. Although Gal-3 and Gal-9 ligands could also potentially bind Gal-1, requirement for melanoma cell Gal-1 ligands was established by preincubating and growing cells in the presence of Gal-1hFc (or hFc control) to bind ligand and interfere with native Gal-1-binding in the Matrigel. Moreover, Gal-1 dependence and galectins in general were substantiated by adding lactose in the assay buffer and in the ECM preparation. Although migration of control A375 and B16 cells treated with hFc was observed, preincubation with Gal-1hFc significantly reduced migratory activity (Figure 6b–e). To our surprise, MCAM^{KD} A375 cell migratory activity was severely blunted even in the absence of Gal-1hFc, implicating additional non-Gal-1-binding functions (Figure 6b and c; $P < 0.001$). MCAM^{KD} B16 cells also exhibited blunted migratory activity when compared with control cells ($P < 0.001$), but migration was further reduced in the presence of Gal-1hFc ($P < 0.01$; Figure 6d and e). ST6^{O/E} A375 and ST6^{O/E} B16 cell migration was also attenuated compared with control cells and was further inhibited by Gal-1hFc pretreatment ($P < 0.01$). These results suggested that melanoma cell Gal-1 ligands and Gal-1 in ECM were important, in part, for effective migration that mirrored data on the role of Gal-1 in ovarian tumor cell adhesion to ECM (Skrincosky et al., 1993).

DISCUSSION

Studies from a number of laboratories show that Gal-1, whether distributed from tumor cells or the host, is critical for melanoma growth. Gal-1 can suppress effector T-cell function and antitumor immunity (Ilarregui et al., 2009; Banh et al., 2011), as well as trigger proangiogenic activity in melanomas (Thijssen et al., 2006, 2008, 2010). There are corresponding binding activities between Gal-1 and its counter-receptor glycoprotein ligand(s) to convey these protumorigenic properties. As demonstrated on immune cells and ECs, Gal-1 ligands commonly display poly-*N*-acetyllactosamines on their N- and/or O-glycans. CD7, CD43, CD45, CD146, and vascular endothelial growth factor receptor 1, for example, are well-described T-cell, dendritic cell, or EC Gal-1 ligands that, upon Gal-1-binding, transmit signals that help induce immunoregulatory, proapoptotic, prosurvival, or proangiogenic activities (Hernandez et al., 2006; Fulcher et al., 2009; Cedeno-Laurent et al., 2010, 2012a,c; Jouve et al., 2013; Crocì et al., 2014; Suzuki et al., 2005a,b). Interestingly, analysis of melanoma cell Gal-1 ligands and their glycosyltransferase regulator(s) and relationship to melanoma malignancy has not been formally addressed.

Here, we studied the expression, identity, and regulation of Gal-1 ligands on melanoma cells. Our data implicate melanoma Gal-1 ligands, notably N-glycosylated MCAM, and Gal-1-binding O-glycans negatively regulated by α 2,6 sialyltransferase ST6GalNAc2 as protumorigenic factors on

melanoma cells. Prior data, in fact, show that MCAM expression directly correlates with melanoma metastasis (Luca *et al.*, 1993; Xie *et al.*, 1997; Mills *et al.*, 2002; Kim *et al.*, 2012) and ST6GalNAc2 also acts as a negative regulator of breast cancer metastasis by forming non-Gal-3-binding sialylated Core 1 O-glycans (Murugaesu *et al.*, 2014). Our findings further highlight MCAM as a Gal-1 ligand and ST6GalNAc2 as a regulator of Gal-1 ligand activity in the glyco-pathogenesis of melanoma growth.

Using Gal-1hFc chimera, we probed Gal-1 ligands on melanoma cells by IF, flow cytometry, and western blotting. Although the glycan-binding repertoire of Gal-1hFc is not identical to human Gal-1 (Cedeno-Laurent *et al.*, 2010), Gal-1hFc upholds hallmark *N*-acetylglucosamine-binding activity and binds the same glycoproteins as human Gal-1 as shown here and elsewhere (Cedeno-Laurent *et al.*, 2010, 2012a,b; Barthel *et al.*, 2011). Although a potential limitation of this study, Gal-1hFc can interrogate human Gal-1 ligands without the need for structure stabilizers. Although efforts using native Gal-1 do exist (Kaltner *et al.*, 1997; Andre *et al.*, 1999; Plzak *et al.*, 2000), native human Gal-1 is problematic for the use in bioassays due to rapid oxidative deactivation and the need for reducing chemicals, complicating interpretation of ligand-binding data. Previous studies using alkylation-induced stabilization or cysteine-less Gal-1 mutants illustrate other methods used to circumvent drawbacks of probing with native Gal-1 (Powell and Whitney, 1984; Inagaki *et al.*, 2000; Nishi *et al.*, 2008; Stowell *et al.*, 2009).

Our initial assessments focused on whether Gal-1 ligands were differentially expressed on melanocytes in normal human skin and in human benign and malignant melanocytic specimens. While routinely detecting Gal-1 ligands on melanoma cells, including metastases, radial and vertical growth phase subsets, and melanoma *in situ*, we did not observe a similar high level of Gal-1 ligand staining on S100⁺ cells in the epidermis of normal skin or adjacent uninvolved skin in melanoma lesions. As normal melanocytes are part of the S100⁺ cell population in the skin, these data indicated that normal melanocytes expressed low levels of Gal-1 ligand. The lack of Gal-1 ligand detection in HEM cell lysates supported this notion. We did, however, detect dermal nests of Gal-1 ligand⁺ S100⁺ cells in a premalignant atypical nevus lesion, suggesting that Gal-1 ligand expression may correspond with transition to malignancy. Further IF studies on other premalignant lesions, including melanoma mimics, are needed to strengthen the speculation that Gal-1 ligands are biomarkers of malignancy.

By performing Gal-1-affinity chromatography and mass spectrometry of protein isolates, we were able to identify that MCAM was a major ligand on melanoma cells. LAMP-1 and -2 and carcinoembryonic antigen were also identified, although they were relatively less abundant. Analysis of Gal-1 ligand activity on MCAM^{KD} melanoma cells revealed that MCAM, indeed, contributed to a significant portion (35%) of total cellular ligand activity. Furthermore, Gal-1 weak binding to de-N-glycosylated MCAM demonstrated that MCAM Gal-1 ligand activity was largely dependent on its N-glycans.

As de-N-glycosylation and protease treatment data suggested that a residual Gal-1-binding activity was expressed on melanoma cells, we explored the potential contribution of O-glycans. Given that α 2,6 sialyltransferase ST6GalNAc2 can prevent Core 2 O-glycan formation (Marcos *et al.*, 2004) and related Gal-1-binding Core 2 structures (Nguyen *et al.*, 2001; Earl *et al.*, 2010), we first examined whether ST6GalNAc2 was differentially expressed in Gal-1 ligand^{lo} HEM and Gal-1 ligand^{hi} melanoma cells. We observed consistent downregulation of ST6GalNAc2 in Gal-1 ligand^{hi} melanoma cells compared with HEMs, implicating its potential role in blocking Gal-1 ligand activity conferred by O-glycans (as illustrated in Figure 5f). This notion was solidified by assaying for Gal-1 ligand expression and *L. esculentum* binding in ST6^{O/E} A375, G361, and/or B16 cells, whose Gal-1 ligand activity and *Lycopersicon esculentum* lectin binding were lowered, implicating other non-MCAM O-glycan-bearing proteins, such as LAMP-1, as constituents of cellular ligand activity (Carlsson *et al.*, 1993; Ohannesian *et al.*, 1994).

In vivo data using MCAM^{KD} and ST6^{O/E} melanoma cells suggested that MCAM functioned as a protumorigenic factor and ST6GalNAc2 served as a negative tumorigenic regulator in collaboration with host Gal-1. Although Gal-1 produced by melanoma cells has a role in immunoregulation and angiogenesis (Rubinstein *et al.*, 2004; Thijssen *et al.*, 2006, 2010; Cedeno-Laurent *et al.*, 2012b,c), *in vivo* results shown here indicated that host Gal-1 was critical for MCAM- and ST6GalNAc2-dependent tumor growth. Growth of MCAM^{KD} or ST6^{O/E} melanoma cells in wild-type mice suggested that melanoma-derived Gal-1 was incapable of fully compensating for the lack of host Gal-1. In fact, our MCAM^{KD} tumorigenicity data in wild-type mice paralleled prior work (Wu *et al.*, 2008) and strengthened our contention that, when binding partner Gal-1 is deficient in mice, can dependency on MCAM Gal-1 ligand activity for robust melanoma growth be appreciated.

In migration assays, Gal-1 ligand neutralization and lactose treatments supported the concept that melanoma Gal-1 ligands helped confer migratory activity. Hence, evaluations on the relative migratory activity of MCAM^{KD} and ST6^{O/E} melanoma cells indicated that MCAM expression and ST6GalNAc2 downregulation were critical for optimal Gal-1 ligand-mediated migratory activity. Because MCAM deficiency abrogated migration below Gal-1 ligand neutralization of control cells, we speculate that additional non-Gal-1 effects could have been affected by MCAM deficiency. Indeed, MCAM has been shown to affect cell morphogenesis (Zeng *et al.*, 2012) or the function of vascular endothelial growth factor receptor (Jiang *et al.*, 2012) that is required for optimal migration in this assay system (Frank *et al.*, 2011). Of note, Gal-1hFc-binding of melanoma cell Gal-1 ligands in solution did not, itself, promote migration, suggesting that Gal-1 immobilized within ECM may be more efficient at forming lattices and triggering a migratory activity on melanoma cells. Further studies are underway to dissect Gal-1-dependent signaling in melanoma cells through MCAM and other Gal-1 ligands.

In summary, observations herein advance the hypothesis that Gal-1/Gal-1 ligand axis is critical for melanoma development, while providing firm insights into the intrinsic role of Gal-1 ligands on melanoma cells. Our data now implicate the influence of Gal-1 on the malignant behavior of melanoma cells through engagement of its Gal-1 ligands. Results now raise the possibility that malignant progression is controlled by expression of Gal-1 ligands, such as MCAM among other membrane glycoproteins, and partially by negative regulator, ST6GalNAc2. These findings have invigorated further inquiry on the glyco-molecular transition of normal and premalignant melanocytes to malignant melanocytes and whether Gal-1 ligand expression can help discriminate malignant melanoma from tumor mimics. This report expands our perspective on the glyco-pathogenesis of malignant melanoma and strengthens the use of Gal-1 antagonists, such as neutralizing antibodies, as therapeutically efficacious reagents to treat malignant melanoma.

MATERIALS AND METHODS

Cells

Please see Supplementary Materials and Methods section online for extensive list of human and mouse cells, methods of cell acquisition, validation of authenticity, and institutional approvals.

Immunofluorescence

Archival formalin-fixed, paraffin-embedded normal human skin, benign melanocytic tumors, and malignant melanoma specimens were obtained in accordance with the approval of Institutional Review Board, stained with hematoxylin and eosin, and analyzed by IF. Studies consisted of tissues from human normal skin ($n=3$), benign nevi ($n=3$), a combined atypical nevus and atypical spindle cell proliferation with inflammation, a malignant melanoma *in situ*, and primary malignant melanomas ($n=5$). In addition, tissue microarray sections containing 56 primary melanomas, 20 metastatic melanomas, and 24 benign pigmented lesions were obtained commercially (BioMax, Rockville, MD). Following deparaffinization and antigen retrieval using EDTA (pH 8), sections were treated with hydrogen peroxide for 5 minutes, protein block for 30 minutes, and then dual stained with rabbit polyclonal anti-S100 (clone Z0311; 1:400; Dako, Carpinteria, CA) or rabbit IgG anti-human CD8 (1:2,000; Abcam, San Francisco, CA) and/or Gal-1hFc or dmGal-1hFc (each at $50\mu\text{g ml}^{-1}$) for 1 hour at room temperature as previously described (Cedeno-Laurent *et al.*, 2010, 2012b). Slides were incubated for 30 minutes with a cocktail of Cy-3 anti-rabbit IgG (1:500) (Invitrogen) and with allophycocyanin goat Fab anti-hFc (1:500) (Jackson ImmunoResearch, West Grove, PA) and counterstained with 4',6-diamidino-2-phenylindole. Slides were treated with ProLong Gold Anti-Fade (Invitrogen, Carlsbad, CA) before fluorescence microscopy. Staining was analyzed with a BX51/BX52 microscope and images were acquired using a Nikon eclipse Ti microscope and a Nikon FDX-35 digital camera (Nikon, Tokyo, Japan) and analyzed using CytoVision 3.6 software (Applied Imaging, San Jose, CA).

Fluorescence analysis of tissue microarray-stained slides was performed using Spot Advanced software (Sterling Heights, MI). Representative core fields at $\times 10$ magnification (encompassing >85% of each core) were analyzed using semiquantitative raw

intensity analysis with NIH Image J software (<http://imagej.nih.gov/ij>). Please see Supplementary Materials and Methods section online for detailed description of immunofluorescence procedures, type and number of analyzed tissues, and method of quantification.

Lectin-affinity chromatographic, mass spectrometry, and western blot analysis

Protein G-affinity chromatography of Gal-1 ligands was performed on human G361 melanoma or control human activated T-cell lysates using Gal-1hFc or nonbinding dmGal-1hFc probes (Cedeno-Laurent *et al.*, 2010) incubated in a ratio of $100\mu\text{g lysate}/2\mu\text{g}$ for 18 hours at 4°C . Eluates were washed extensively in lysis buffer containing 2% NP-40 and in phosphate-buffered saline. For Gal-1 ligand identification, eluates from Gal-1hFc- or dmGal-1hFc-protein G chromatography of G361 lysates were analyzed by tandem mass spectrometry by the Beth-Israel Deaconess Medical Center Mass Spectrometry Core Facility (Boston, MA).

For western blot analyses, whole-cell lysates, Matrigel, eluates from dmGal-1hFc/Gal-1hFc/protein G chromatography and immunoprecipitates using anti-MCAM (clone P1H12; Lifespan Biosciences, Seattle, WA), anti-MCAM (EPR3208; EMD Millipore, Billerica, MA), anti-CD45RO (UCH-L1; Santa Cruz Biotechnology, Dallas, TX), anti-LAMP-1 (clone H4A3; BioLegend, San Diego, CA), anti-90K/MAC-2BP (clone SP-2; a generous gift from Dr Stefano Iacobelli, MediaPharma Srl, Chieti, Italy) (Iacobelli *et al.*, 1986), or isotype control antibody were prepared, separated on reducing 4–20% SDS-PAGE gradient gels (Bio-Rad, Hercules, CA), and transferred to immunoblot polyvinylidene difluoride membrane (Bio-Rad) as previously described (Cedeno-Laurent *et al.*, 2012a). Where indicated, anti-MCAM immunoprecipitates were treated with Peptide-N-Glycosidase F (PNGase) as per the manufacturer's protocol (New England Biolabs, Ipswich, MA). MCAM, CD45RO, Gal-1 ligands, SOX10, Gal-1, and LAMP-1, MAC-2BP, and β -actin were western blotted with anti-MCAM (P1H12 or EPR3208; $1\mu\text{g ml}^{-1}$), anti-CD45RO (UCH-L1; $1\mu\text{g ml}^{-1}$), Gal-1hFc ($10\mu\text{g ml}^{-1}$), nonbinding mutant dmGal-1hFc ($10\mu\text{g ml}^{-1}$), goat polyclonal anti-SOX10 (Santa Cruz Biotechnology) ($1\mu\text{g ml}^{-1}$), goat polyclonal anti-mouse/human Gal-1 ($2\mu\text{g ml}^{-1}$; R&D Systems, Minneapolis, MN), anti-LAMP-1 (H4A3), anti-90K/MAC-2BP (clone SP-2), or anti- β -actin ($1\mu\text{g ml}^{-1}$; BD Biosciences, San Jose, CA), respectively, then incubated with relevant alkaline phosphatase-conjugated secondary antibody (Jackson ImmunoResearch) and developed with Western Blue alkaline phosphatase substrate (Promega, Madison, WI) as previously described (Cedeno-Laurent *et al.*, 2010). Alternatively, blots were incubated with IRDye-800CW anti-hlgG, IRDye-800CW anti-rabbit IgG, or IRDye-680RD anti-mouse IgG and analyzed on a LI-COR Odyssey Imaging System (LI-COR Biosciences, Lincoln, NE).

Real-time quantitative reverse-transcriptase-PCR analysis of galectins

Please see Supplementary Materials and Methods section online for detailed procedures on real-time quantitative reverse-transcriptase-PCR.

Silencing of MCAM

Please see Supplementary Materials and Methods section online for detailed procedures on stable MCAM silencing in cells.

Overexpression of ST6GalNAc2

Please see Supplementary Materials and Methods section online for detailed procedures on stable ST6GalNAc2 overexpression in cells.

Flow cytometry

Please see Supplementary Materials and Methods section online for detailed procedures on FACS analysis and glyco-metabolic inhibitor treatments.

Melanoma cell migration assay

Melanoma cells were plated and cultured on Matrigel, an ECM preparation from a mouse sarcoma and a rich source of Gal-1 (Crocini et al., 2012) as previously described (Frank et al., 2011). The presence of Gal-1 in Matrigel preparations was validated by western blot analysis (Supplementary Figure S9 online). Negative controls consisted of adding 50 mM lactose to Matrigel and assay medium or pretreating melanoma cells with saturating levels of Gal-1hFc (Cedeno-Laurent et al., 2010).

Before assays, melanoma cells were cultured for 24 hours in RPMI-1640/10% fetal bovine serum/1% penicillin/streptomycin with 50 mM lactose to elute prebound melanoma-derived Gal-1, inhibit melanoma cell Gal-1 ligand engagement, and silence Gal-1 ligand-dependent cellular events. Cells were then harvested with 1 mM EDTA, washed 3 × in phosphate-buffered saline, suspended in RPMI-1640/10% fetal bovine serum/100 ng ml⁻¹ recombinant human or recombinant mouse VEGF (R&D Systems), and seeded at 2 × 10⁴/well in 24-well plates coated with growth factor-depleted Matrigel (BD Biosciences). Where indicated, Gal-1hFc, hFc control, or 50 mM lactose control was added to occupy and competitively inhibit melanoma cell Gal-1 ligand binding to native Gal-1 in Matrigel. Tube-like cellular formation, which corresponds with melanoma virulence (Frank et al., 2011), was examined by phase-contrast microscopy after 72 hours. Tube-like formations defined as ≥2 cells forming elongated structures were counted at 10× magnification from 4 different fields for each condition. Experiments were conducted at least 3 times.

In vitro melanoma cell proliferation assay

Please see Supplementary Materials and Methods section online for detailed procedures on the melanoma cell proliferation assay.

Melanoma growth in mice

Scr or vector control, MCAM^{KD}, or ST6^{O/E} B16 melanoma cells (1 × 10⁵) were inoculated subcutaneously in the left flank of wild-type or Gal-1^{-/-} C57BL/6 mice (The Jackson Laboratory, Bar Harbor, ME). Tumor growth (*n* = 8/experiment) was measured every other day using calipers. All animal experiments were authorized by the institutional animal care and use committee, and mice were killed as per their guidelines. Experiments were repeated 3 times.

Statistical analysis

Statistical significant comparisons were ascertained by two-tailed Student's *t*-test, a paired *t*-test, one-way analysis of variance with Dunnett's *post test*, or contingency table on GraphPad Prism (GraphPad Software, La Jolla, CA).

CONFLICT OF INTEREST

AAQ consults for Abbvie, Amgen, Novartis, the Centers for Disease Control and Prevention, Janssen, and Merck, and serves as an investigator for Amgen. The other authors state no conflict of interest.

ACKNOWLEDGMENTS

We thank John Asara and Ming Yuan from the BIDMC Mass Spectrometry Core facility, which is partially funded by NIH-shared instrumentation grant 1S10OD010612 (J Asara), for acquiring and analyzing the MS identification data.
